This paper discusses the current state-of-the-art, ongoing fundamental and technical challenges and potential roadmaps for micro-scale vibration energy harvesting (VEH) and power conversion devices employing micro/nano-magnetics. Such devices are of paramount importance as powering solution for autonomous and ubiquitous sensor nodes within the emerging ‘Internet of Things - IoT’. In this paper, we have reviewed the fundamental limitations, technological needs and breakthroughs in the mentioned areas including materials, process integration and device design issues. Particularly, current limitations in both relevant soft and hard (or permanent) micro-magnets, roadmaps for a complete ‘Magnetic MEMS’ solution for energy harvesting and efficient low power conversion for ‘IoT’ applications are discussed.

***Index Terms*—Vibration energy harvesting, Micro/nano-magnetics, MEMS, Permanent Magnets, Soft Magnetic Materials, Power management.**

I. INTRODUCTION

THE RECENT developments in low-power electronics and the explosion of ICT technologies to provide exceptionally fast services that can facilitate the regular lifestyle of citizens has boosted up the paradigm of ‘Smart City’, the vision encircling a plethora of connected objects exchanging information among each other [1-3]. Here, the goal is to make our surroundings more responsive, safer and healthier while improving the energy efficiency through bounded utilization of the resources. The integral component in transpiring the vision of ‘Smart City’ is the ‘Internet of things - (IoT)’ which is considered as one of the fastest growing technological platforms comprising of a grid of spatially distributed Wireless Sensor Nodes (WSNs) that can sense and communicate information among each other and with the end-users. It has been quite aptly projected that there will be over 50 billion of wirelessly connected devices by 2020 [4], and it will be widely used in in-situ health monitoring [5], structural health monitoring of various civil structures [6] and in other commercial and military applications [7], where it is very impractical to replace or replenish the depleted energy in the batteries. Therefore, perpetually powering these billions of deployed sensor nodes is actually the critical bottleneck in the materialization and deployment of the WSNs. In this predicament, harvesting energy from ubiquitous ambient mechanical vibrations to generate sustainable electricity for powering the WSNs is gradually becoming an attractive alternative to the conventional, energy-limited and environment polluting batteries due to their wide abundance in the nature.

The vibration-based energy harvesters (VEHs), consisting of a mechanical oscillator, a transducer and power conditioning circuitry, scavenges the ambient mechanical energy and

converts it into usable power employing suitable transduction mechanisms such as Piezoelectric [8-11], Electrostatic [12-15], Triboelectric [16-17], and Electromagnetic [18-21]. In piezoelectric materials, the external mechanical excitation causes strain of the active materials and an electric polarization proportional to that strain arises at the boundaries of these materials that can be obtained as usable voltage across the electric load. Though these piezoelectric harvesters offer simplicity in implementation using existing matured fabrication techniques at both macro- and micro-scales along with relatively higher power density [22], but the reliance of device performance on the material properties doesn’t allow easy alterations of the different parameters controlling the device performances. Moreover, the ‘electric fatigue’ [23] resulting in reduced switching polarization after few cycles of operation and the brittle nature [24] of the popular ceramic piezoelectric materials (e.g. PZT) along with their inherently very high impedance limit the performance of these piezoelectric VEHs. In case of the electrostatic generators (also known as capacitive EHs), electrically charged components move with respect to each other performing work against the electrostatic forces which can be harvested in the form of varying potential. These harvesters have good compatibility with the MEMS/CMOS fabrication techniques [25] but the low output current and the need of external DC bias or pre-charged electret membranes are few of its major demerits. In the past few years, the triboelectric effect based mechanical EHs have drawn significant research attention. It relies on the principle of charge generation on the surface of a family of materials (organic or inorganic) after contact (Vertical contact or lateral sliding type contact) which drives the flow of mobile charges and hence current between the electrodes under vibrations. This particular mechanism has been proved to be providing highly efficient transducers,

especially in low-frequency domains (ideally for human motion harvesting applications). The attractive attributes are its immensely simple and cost-effective fabrication [26] technique using next generation materials. However, such techniques are difficult to implement for inertial VEH systems and suffers from very high input impedance.

On the other hand, the electromagnetic vibration energy harvesters (EM VEHs) utilize the relative motion between permanent magnet and coil which induces current into the coil, thereby harnessing power from environmental vibrations. The EM transducers are characterized by low internal (coil) resistance, moderately low output voltage and high output current [27]. While the macro/meso-scale implementation of EM VEH devices is well explored and provide better performances among all the transduction mechanisms [28-33], but the micro-scale implementation of such devices remains as a challenge. This could be mainly attributed to two facts – increase of coil loss at the micro-scale and lack of high-performance micro-magnets required for such devices. These facts have restricted the number of reported works in this particular area considerably compared to the piezoelectric or electrostatic MEMS generators. On the brighter side, EM generators do not require complex biasing mechanisms as in the case of electrostatics. Also, the reliability/longevity of this type of transducers is significantly better than the others which is extremely critical for any EH based systems [34]. There has been a number of review paper published over the years that have addressed the scaling issues associated with the EM VEH devices [35-37]. Unfortunately, most of them have dealt with literatures related to conventional EH devices only. However, in order to build a realistic roadmap, it is essential to look beyond the state-of-the-art of VEH devices and to consider the tremendous advancements in the field of micro/nano-magnetics over the past few years. Such technological advancements could potentially open up new routes for developing highly miniaturized magnetic generators with impressive power density which is absolutely essential in the context of the upcoming ‘IoT’ era.

Hence, this paper discusses and scrutinizes the different aspects of the magnetic EH devices and also addresses the crucial limitations in the micro-scale development of such devices in detail. Following that, outlooks and roadmaps for improving the device performance at miniaturized scale incorporating micro/nano-magnetics is provided. Finally, the important role of magnetics in efficient power conversion of EH devices is briefly discussed.

II. REVIEW OF THE STATE-OF-THE-ART MEMS BASED EM VEH DEVICES

Unlike other transducers, MEMS based EM VEH devices can be divided into three categories according to their level of integration – (1) Fully MEMS integrated, (2) MEMS suspension with micro-coil and (3) MEMS suspension only. Most attempts to incorporate permanent magnets using

microfabrication techniques such as sputter deposition [38-40], electrodeposition [41-42] or magnetic powder bonding [43-46] in EM VEH have resulted in very low output power (few pW - nW) level. Jiang et. al. [38] reported a fully integrated MEMS EM energy harvester by bonding a vibrator with embedded micro-magnets and a stator with integrated micro-coils. The micro-magnets are fabricated by using sputtering deposition of NdFeB/Ta multilayered magnetic films with a thickness of 10 μm . The maximum power output of the energy harvester at 115 Hz is approximately 12 nW at an input acceleration of 1.17g. Han et. al. [41] reported an in-plane moving MEMS EM generator where CoNiMnP hard magnetic alloy is electroplated onto the vibration plate instead of manually assembling bulk magnets. The in-plane device with such integration approach condenses the device's volume to 67.5 mm^3 . The proposed structure with an integrated magnet array can generate 11.2 nW maximum output power at a frequency of 48 Hz with a matched load of 15.8 Ω . Wang and Arnold [43] reported three different designs of integrated EM harvesters that utilize embedded NdFeB powder micro-magnet technology whereas a PDMS diaphragm acts as the resonator. The structures with among the smallest volume (4 – 15 mm^3) magnetic generators reported to date, produce very little load power even at a reasonably high acceleration. A novel fully integrated micro-scale EM device using micro-patterning of bonded magnets was reported by Tao et. al. [44]. The magnetic material utilized is a polymer composite, consisting of a commercially available NdFeB powder dispersed in epoxy. The prototype (20 mm^3) is fabricated using UV-LIGA technology and micro-electroplating technology. The fabricated device can generate a maximum peak-peak voltage of 20.9 μV at the device's resonance frequency of 365 Hz and input acceleration of 1g.

In other approaches, the micro-coil is integrated on to the moving silicon paddle which experiences a varying magnetic field due to the relative motion with respect to static NdFeB bulk magnets [47-55]. The output power is also found to be low in such cases due to poor magnetic flux linkage and smaller proof mass. Liu et. al. [47] reported a micro-scale ultra-wide bandwidth device, where the peak output power from the device is significantly low due to the above-mentioned reasons. The same group from the National University of Singapore has reported a number of other topologies [48-51], where in spite of the interesting device dynamics, the final output power is quite low due to the similar drawbacks. Recently, Zhang et. al. [53] developed two micro-fabricated devices (one with a coil proof mass and the other with a magnet proof mass) suspended by silicon springs. Rapid spatial variations of magnetic field are produced by alternately polarized NdFeB magnet array and are coupled and aligned to an array of multiple-turn spiral coils. Experimental results show that the EH with a coil proof mass generates an induced peak-peak voltage of 18.2 mV with 0.75 μW power output (into 13.8 Ω load) when it is vibrated at 410 Hz with a vibration amplitude of 6.7 μm (corresponding to 4.5g acceleration). The other device with a magnet array proof mass generates a voltage of 16.8 mV with 0.82 μW power output

(into 10.8 Ω load) when it is vibrated at 350 Hz with a vibration amplitude of 9.1 μm (corresponding to 4.5g acceleration).

It is quite straight-forward to batch-fabricate the mechanical suspension using standard silicon MEMS processing. However, the high Young's modulus of silicon (resulting in higher resonance frequency) has encouraged the researchers to exploit other low Young's modulus polymer materials like parylene [56-57] and PDMS [43, 58] for developing the resonating spring structures. Other than polymers, metallic mechanical structures have also been explored. These include electroplated Ni spring [59-60], and wet-etched copper foil [61] to name a few. It can be concluded from this review that high flux linkage through proper configurations of magnet and coil, along with development of suitable MEMS components, are essential to improve the performance of micro-electromagnetic EHs.

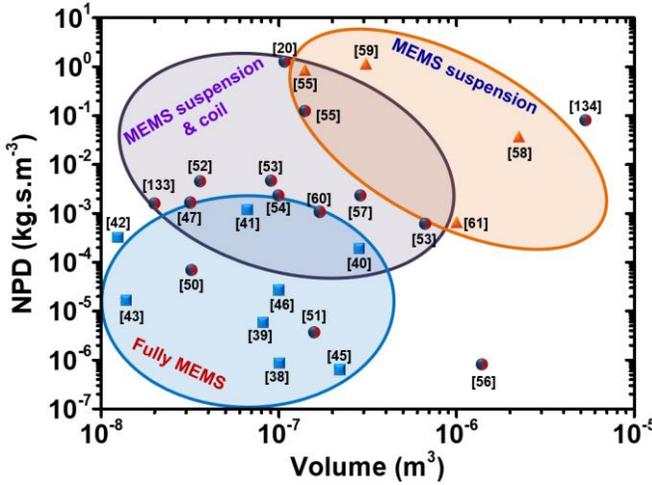

Fig. 1: Comparison of the Normalized Power Density (NPD) of the state-of-the-art MEMS EM VEH literatures in terms of device volume.

Comparing different VEH devices is not straightforward as the amount of data presented in published works varies considerably in terms of their operating conditions such as input acceleration and frequency. Hence, just comparing the output parameters like voltage, current or power is not justified. Beeby et. al. [28] derived a figure-of-merit for resonant VEH devices called, Normalized Power Density (NPD), which is simply the output power (P) of the device normalized w.r.t. input acceleration level (A) and volume (V) of the device.

$$\text{Normalized Power Density (NPD)} = \frac{P}{A^2 V} \quad (1)$$

In Fig. 1, the NPD of different MEMS scale EM VEHs are compared with respect to their device volume. It is to be noted here, we have compared different MEMS scale EM VEH devices regardless of their operating principles, including resonant, multi-frequency and nonlinear EHs. For wideband nonlinear devices, the peak power generated at the down jump frequency is considered which is not fully justified but makes the comparison easy. In terms of the level of integration, the fully integrated MEMS EM harvesters [38-46] have lowest

NPD due to the low efficiency of the integrated magnets. Thus, in most of the reported literatures [47-61], bulk NdFeB magnets are used whereas either or both of the spring structure and pick-up coil are integrated using CMOS compatible MEMS techniques. Coils are mostly integrated on the vibrating elements while a single or an array of static magnets is used to create the varying magnetic field. The output power is found to be low in such cases due to poor magnetic flux linkage and smaller proof mass. As the thickness of the sputtered layers is quite low, the devices incorporating such sputtered metallic coil have lower output. Silicon is the most commonly used material in MEMS devices due to their suitability with CMOS compatible fabrication processes and mechanical robustness. But due to its large elastic modulus ($Y=170$ GPa), the operational frequency becomes high with miniaturization in size. Hence, many researchers have exploited other polymeric materials for developing the spring structure in order to reduce the frequency within the same footprint. The low Young's modulus not only brings the resonance frequency to a lower value but also increases the displacement amplitude as the spring constant is reduced. However, reliability of these materials for long term applications is a concern which is yet to be verified in the reported literature.

III. SCALING ISSUES OF MAGNETIC EH DEVICES - CHALLENGES AND OUTLOOKS

Electromagnetic (EM) energy harvesters have the advantages of low output impedance and high output current levels, but the micro-scale implementation is found to be challenging. It is well-known facts in MEMS that surface related phenomenon have a favorable scaling effect as compared to volume related effects [62]. This is due to the fact that surface (S) scales as the square of length (L) whereas volume (V) scales as the cube of length. Therefore, as L decreases, its S/V ratio increases. Unfortunately, the strength of magnetic flux of a magnet depends on its volume, even though the magnetic flux density available from a permanent magnet is independent of its size. Therefore, EM force is less favorable to scale down compared to electrostatic or piezoelectric forces. There are several reported works that have already demonstrated the effect of scaling laws on the performance of EM generators [35-37]. Arnold [37] derived the power scaling law for oscillatory resonant EM generators. According to [63], the maximum load power at resonance for optimized load value is given as

$$P_L = \frac{m^2 A^2}{8c_m (\frac{R_C c_m}{\gamma^2} + 1)} \quad (2)$$

The source acceleration (A) is independent of the device size whereas the mass (m), mechanical damping co-efficient (c_m), electromagnetic coupling term (γ) and coil resistance (R_C) are proportional to L^3 , L , L and L^{-1} respectively (L – length). By assuming such dependences on L , Arnold derived a generic rule for scaling of load power for EM generators as

$$P \propto \frac{L^7 A^2}{L^2 + 1} \quad (3)$$

or
$$NPD \propto \frac{L^4}{L^2+1} \quad (4)$$

where, NPD is the normalized power density. Two asymptotic relations are obtained due to the summation in the denominator.

$$NPD \propto L^2 \text{ for } L \rightarrow \infty \quad (5)$$

$$NPD \propto L^4 \text{ for } L \rightarrow 0 \quad (6)$$

It is also explained that if electrical damping ($c_e \sim \frac{\gamma^2}{R_C}$) dominates over mechanical damping (c_m), according to equation (3) and (4), the NPD scales according to equation (5) whereas if c_m is dominant over c_e , then the power scales according to equation (6). By comparing the dimension of the two damping terms, it was concluded that the mechanical damping will be dominating at very small scale (micro/nano) and electrical damping will dominate at very large scale (macro/meso). Hence, the power output from a MEMS scale oscillatory generator (most common type of MEMS transducer) is restricted by large mechanical damping as the mass and velocity decrease. This indirectly owes to the inability to produce large electromagnetic coupling at the MEMS scale. The electrical damping term for EM generators are given as [28, 63]

$$c_e = \frac{n^2 \left(\frac{d\phi}{dz}\right)^2}{R_C + R_L + j\omega L_C} \quad (7)$$

The drastic drop of this damping value with size scaling can be attributed to each term on the right-hand side of the above equation. While number of turns (n), coil resistance (R_C) and coil inductance (L_C) are related to the development of miniaturized coils, the magnetic flux gradient ($\frac{d\phi}{dz}$) is related to the rate of change of magnetic flux w.r.t. to the coil. In the following sections, we will discuss the challenges and possible approaches to improve the contribution from each of these terms to enhance the electrical damping overall, which is critical to the performances of EM generators. From the previous section, we have already seen that the advances in MEMS technology have resulted in a variety of micro-fabricated structures that can be coupled with permanent magnets to develop miniaturized MEMS based EM VEH devices. But practical implementation of a MEMS based micro-power generator involves a number of challenges like the realization of high efficiency, multiple-turn coils and permanent magnets. Also, it is apparent from Fig. 1 that not only the device volume, but level of integration is also a limiting factor for EM generators. Fully integrated MEMS EM VEH devices have much lower NPD compared to the semi-integrated devices despite having same or comparable volume. However, as shown in Fig. 2 and as discussed below, it is possible to achieve reasonable NPD from MEMS-scale EM VEH devices with sophisticated and careful choice of the technologies.

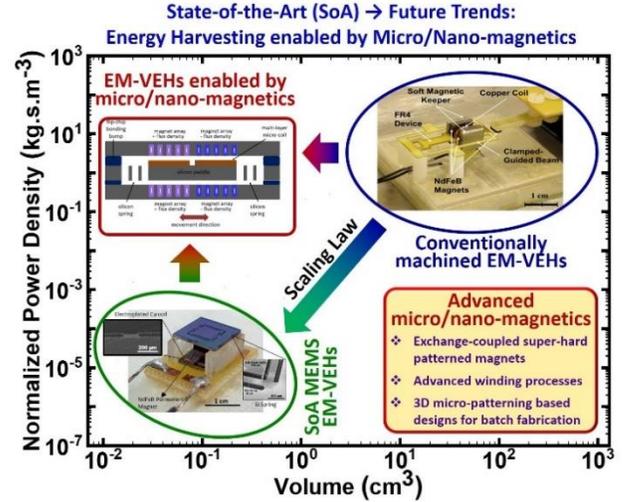

Fig. 2: Vision of high normalized power density (NPD), MEMS EM VEH devices enabled by micro/nano-magnetics.

A. Challenges and Outlooks for the Micro-coil Development

The specific coil parameters (n , R_C , L_C) are strictly dependent on the coil design and dimensions. For a fixed volume of the coil, the coil resistance and inductance are both function of the number of turns. The resistance of a single layer micro-fabricated coil, with equal track-width, track-spacing and track-thickness, is given as [64]

$$R_C = \frac{8\rho_{Cu}(d_o-d_i)}{(d_o+d_i)^2} (4N^3 - 4N^2 + N) \quad (8)$$

Where, ρ is the resistivity of the coil material, N is the number of turns, d_o and d_i are the coil outer and inner diameter respectively. For large values of N , the lower order terms in N in equation (8) can be neglected. Then the coil resistance is (1) proportional to the cube of number of turns (N^3) and (2) inversely proportional to the scaling factor. The number of turns within a given area can be maximized by minimizing the track width and spacing which is, however, limited by limits of the standard optical lithography process. Again, reduction in the track width vis-à-vis coil cross-sectional area effectively increases the coil resistance unless such adverse effect is compensated by developing very high aspect ratio coil structures. The coil inductance (L_C) is also a function of number of turns and coil geometry but the impedance contribution due to the inductance at normal operating frequencies (few Hz to few hundreds of Hz) of VEH devices is negligible compared to that of the resistive component. Hence, the rule of thumb for designing highly efficient micro-coil for VEH application is to increase the number of turns within a certain fixed footprint while maintaining relatively low resistance.

In some of the reported literatures of EM VEH, sputtered metallic (Al, Au, Cr) coil is used to induce electrical voltage. Liu et. al. [50] reported in-plane moving EM harvesters where two layers of Al coil are sputtered onto the movable silicon structure. Similar sputtered, double layer coil is used in other works as well [47-49,51]. Recently, Tao et. al. [52] have used a

planar Cr/Au sputtered coil (350 nm thick). Generally, the thickness of the sputtered metallic layers is low due to the slow deposition rate and reported sputtered metals such as Al or Au has higher resistivity than copper. All these constraints affect the final output significantly. Electroplated planar copper coils were previously used [53-54] as opposed to sputtered coils to develop thick conducting layers. Zorlu et. al. [57] reported electroplated double layer copper coils with each layer having 41 turns, integrated on a parylene cantilever. Mallick et. al. [55] also reported similar coil, where track width, track spacing and track height of the coil turns are 10 μm each, with overall 144 turns and coil resistance of 190 Ω . Zhang et. al. [134] presented two micro-fabrication approaches for multi-layer coils for vibration energy harvesting applications. In the first conventional approach, 25 μm thick (aspect ratio (height/width) = 0.5) copper is electroplated within photoresist mold where the resulting coil has similar performances as compared to the other photoresist molded copper coils reported. However, the authors developed a novel strategy to increase the aspect ratio vis-à-vis to reduce the coil resistance in their second reported micro-fabrication process. A silicon wafer is etched using deep reactive ion etching (DRIE) to develop a silicon mold which is then used for subsequent copper electrodeposition. 300 μm thick (aspect ratio = 3) coil is developed using that process resulting in a dramatically lower resistance compared to that obtained from coil developed using photoresist mold.

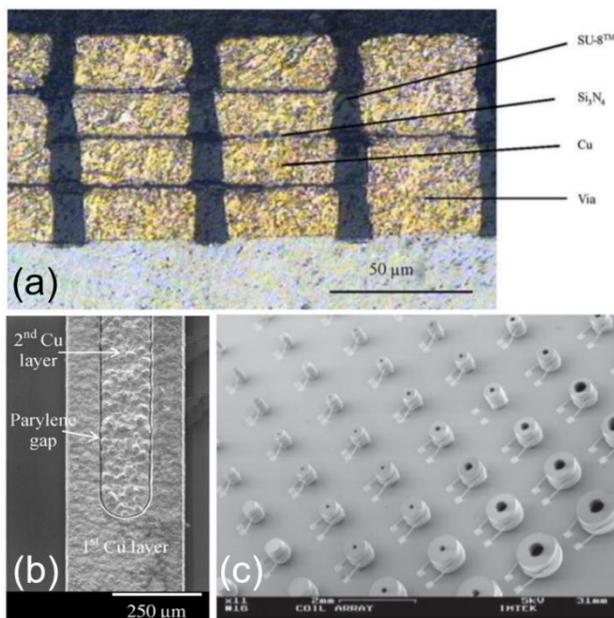

Fig. 3: Methods to improve packing density of micro-coils: (a) high density vertical stacking [69] (courtesy: Springer Nature), (b) high density lateral stacking [70] (© 2010 IEEE), (c) 3D micro-coil [71] (courtesy: IOP publishers).

Micro-coils are being used in a number of other MEMS applications over the years such as micro-inductors/transformers [65-66], sensors [67] etc., where the requirements are similar to that for EM VEH application.

Hence, micro-winding technology has evolved significantly in past decade or so. Unfortunately, most of such advancements are yet to be exploited for VEH application. One way to improve the micro-coil performance is by developing high aspect ratio (HAR) coil conductor structures. Most reported micro-coils in VEH literature have aspect ratio between 0.2 to 1. The main limitation for developing high aspect ratio structure is in the photoresist processing. Normally slow spin-rate is needed to develop thick photoresist profile which does not work so well for smaller resolution pitch sizes. Also, multiple spinning steps are needed to develop thick resist mold using most positive photoresists which further degrade the resist profile. Recently, Anthony et. al. [68] reported an optimized photoresist process using negative tone THB-151N resist to achieve one of the highest aspect ratio (17) and resolution (~5 μm) resist patterns for fabrication of thick (~85 μm) micro-winding in a single spin step. They showed a near-vertical (~91°) electroplated copper side-wall profile.

Another way of improving micro-coil efficiency for VEH applications is to increase the number of coil turns/packing density of conductors within a fixed volume. Ruffert and Gatzen [69] developed a fabrication process by which they developed multilayer micro-coil with as many as four vertical layers (Fig. 3(a)) while the separation between subsequent coil stack is created by thin (500 nm) Si_3N_4 deposition using Plasma Enhanced Chemical Vapour Deposition (PECVD). However, the authors raised concerns regarding the complexity of the process as it required 13 mask steps involving ten lithographic masks. While vertical packing density can be enhanced using the above-mentioned process, it is advantageous to improve the lateral packing density as then the overall packing density can be improved by achieving multilayers of such coil. Herrault et. al. [70] reported such micro-fabrication process where ultra-dense micro-coil (Fig. 3(b)) is developed by electroplating copper in the gap between adjacent turns with all copper strips are separated from each other by a thin parylene coating. Usage of parylene compared to Si_3N_4 has two-fold advantage. Firstly, deposition of parylene is relatively low-cost compared to PECVD deposition of Si_3N_4 and secondly parylene is deposited in a conformal manner allowing more reliability in terms of insulation between two adjacent copper structures. The authors also found out that the device with a 5 μm thick parylene layer exhibited a voltage breakdown of approximately 1800 V or 360 V/ μm . Kratt et. al. [71] reported the MEMS compatible fabrication of 3D micro-coils made with an automatic wire bonder. Using UV lithography, high aspect ratio SU-8 posts with diameter of 100 μm are developed that serve as mechanical stabilization yokes for the coils. Then they employed wire bonder to wind 25 μm insulated gold wire around the posts in a solenoidal path, yielding arrays of micro coils. Each micro coil is bonded directly on-chip, so that loose wire ends are avoided. Arrays of such coils (Fig. 3(c)) can be developed in a very short time by serially driving the wire bonder and the process can maintain a high throughput. However, even though large number of turns can be achieved using this method, the process

is applicable for 3D coils only whereas almost all the reported works on EM VEHs focuses mainly on planar coil. Therefore, it is necessary to consider the impact of the geometry of the coil on the magnet-coil interaction.

B. Challenges and Outlooks for the Micro-magnet Development and Integration

The difficulty in miniaturization and integration of the high-performance permanent magnets in MEMS scale devices hinders the continuous demand of increasing power density (= power/device volume) as it is apparent from the literature review of previous section. Permanent (or hard) magnets are ferromagnetic materials that possess strong magnetization in the absence of an external magnetic field. Once magnetized, they can provide a free source of magnetic fields without any requirement of external power. The desirable properties of permanent magnets are given by high coercivity (H_C), high remanence (B_r) values along with high value of the most common figure-of-merit – the energy product $(BH)_{\max}$ – which is area of the largest B-H rectangle that can be constructed within the second quadrant of the hysteresis curve. In general, CMOS compatible development of high energy product $(BH)_{\max}$ permanent magnets with thickness of the order of microns to hundreds of microns is a key challenge [72-73]. Here we will first discuss the recent developments in the hard-ferromagnetic (FM) alloys and compounds, also referred to as permanent magnets for MEMS related applications. Then we will go onto the specific design or integration challenges which play crucial roles in micromagnetic devices but are often overlooked.

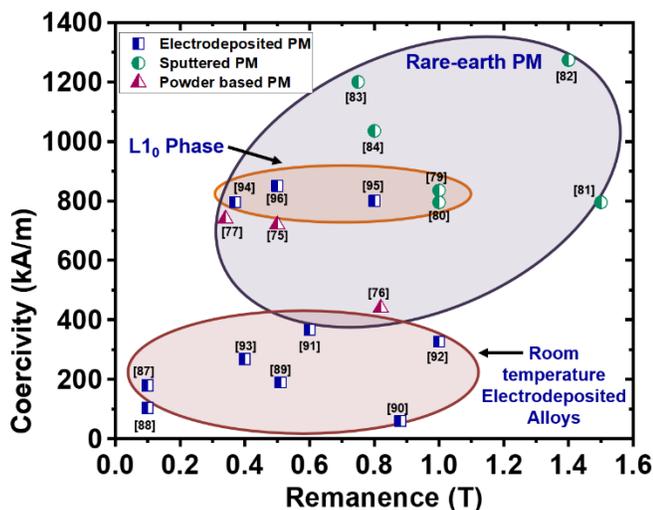

Fig. 4: Comparison between magnetic properties of different permanent magnets reported in literature.

Most modern magnets are made from ferrites (typically Sr or Ba ferrite) or rare-earth alloys (commonly SmCo or NdFeB). However, the market of permanent (or hard) magnets is dominated by sintered, bulk NdFeB (Maximum energy product $BH_{\max} = 450 \text{ kJ/m}^3$ based on the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase) discrete magnets [74], which is manufactured from magnetic powders

using powder metallurgy techniques such as sintering. But the CMOS compatible integration of these materials remains a key challenge due to the need of high temperature processing. Also, the dimensional tolerance value of such powder processed magnets cannot be precisely controlled below certain level (1 mm or so). As a result, bulk-manufactured magnets are often too big for the intended micro-scale applications and additional complexity and cost add up in the precise assembly process. Therefore, several fabrication techniques including powder-based chemo-mechanical fabrication methods [75-78] (dry-packing, screen printing etc.), conventional thin film deposition techniques such as sputtering [79-84], pulse laser deposition (PLD) [85-86], and electrochemical deposition [87-96] have emerged over the years depending on the application requirements. Among the various techniques currently being exploited for integration of permanent magnets in MEMS, electrochemical deposition is an attractive choice due to its low cost and relatively high deposition rate at CMOS permissible temperature. On the other hand, sputtered rare-earth compounds like NdFeB and SmCo are among the best performing micro-magnets which could be deposited at a relatively high rate as well by optimizing the growth process [79-81]. However, sputtering of those alloys are often hindered by the requirements for specialized deposition system and high annealing temperatures.

Growth of face-centred tetragonal (fct) $L1_0$ structure in transition metal alloys Co/Fe-Pt with equi-atomic ratios has received extensive attention due to the high uniaxial magneto-crystalline anisotropy ($K_1 = 6.6 \text{ MJ/m}^3$) and coercivity as high as 800 kA/m or more. Ordered $L1_0$ structure of equi-atomic Co/Fe-Pt films with varying thicknesses have been deposited by sputtering [97-99], PLD [85-86] and electrodeposition [100-102] techniques. However, the phase transformation and the desired hard magnetic properties are obtained at either elevated substrate temperature during deposition (sputtering) or by high temperature, post-deposition annealing (electrodeposition). On the other hand, Co rich Co-Pt alloys with atomic ratio of 80:20 exhibit good hard magnetic properties without any requirement of high temperature annealing step making them a good candidate for CMOS/MEMS integration [91-94]. Such magnetic properties can be availed in the as-deposited state due to the high magnetic anisotropy induced by incorporating Pt in the hexagonal closed-packed (hcp) phase of Co and phosphorus-segregated grain boundaries. But still the hard-magnetic properties (such as coercivity, remanence) of this alloy are inferior compared to afore-mentioned materials. Apart from FePt/CoPt/CoPtP, CoMnNiP [87, 90] and CoNiP [88] hard magnetic alloys have also been investigated and used for magnetic MEMS. They have shown strong perpendicular magnetic anisotropy up to reasonably large thickness but their $(BH)_{\max}$ is smaller compared to the other electrodeposited alloys making them unsuitable for the target applications.

Fig. 4 compares the different magnetic properties of recently developed permanent magnets for MEMS applications. It is to

be noted that both H_C and B_r depends on thickness of the developed magnets. Hence, it is not completely justifiable to compare such properties straight away. However, we have excluded the very thin, nano-scale thickness permanent magnets in the literature, which are not ideal for MEMS related applications. From Fig. 4 we can clearly see that rare earth permanent magnets are superior in performance compared to other reported alloys. While the state-of-the-art non-rare-earth based magnets may be sufficient in applications such as micro-actuators, higher values of H_C and B_r are needed to produce large flux densities required to generate useful amount of power.

To overcome the challenges associated with bulk magnets and limitations of the conventional ‘bottom-up’ deposition techniques, there has been a recent interest in utilizing magnetic powders for the ‘top-down’ development of micro-magnets using wafer-scale processing techniques. Polymer bonded permanent magnetic powders exhibit magnetic performances comparable to their fully dense counterparts. The goal of batch fabrication using standard photolithographic patterning technique can also be achieved using this technique while exploiting the availability of high-quality magnetic powders. Moreover, such a process can easily be adjusted to accommodate different magnetic powders. Previous micro-fabrication efforts were similar to the bulk manufacturing of bonded magnets, where magnetic powders were mixed in a liquid resin or polymer. This powder/liquid mixture is then selectively dispensed, patterned, or molded to form the magnetic microstructure. The major limitation of such process is the significant degradation of the magnetic properties of the bonded magnets compared to the raw powder. This is because the net magnetization (and hence B_r) of a magnetic structure reduces proportionally to the volumetric fill fraction of the magnetic particles in the composite. On the other hand, if excessively high concentration of the powder is added to the composite mixture, that would make it too viscous for spin coating, tape casting, or screen-printing techniques. Additionally, high powder concentration can inhibit successful photolithographic patterning, unless the particle size is relatively smaller compared to the wavelength of the exposure light source (typically 300–400 nm). Other concerns for such technique include agglomeration and settling of the powder in the mixture and reproducibility issues. To overcome such issues, dry-pressed bonded magnet technology has evolved noticeably over the years [75-78]. Here, the pattern transfer is achieved using a low-cost, mechanical doctor blade technique to pack the dry powders in pre-etched cavities in a substrate instead of mixing the magnetic powder into any liquid solution [75]. After dry-pressing, the loosely bound powders are kept in place by either using a polymer capping layer deposition or by using a polymer matrix to strongly bind the powder. Various types of polymer capping layers/matrixes have been developed which include polyimide, SU-8, PMMA, PDMS and wax. Recently, Jackson et. al. [76] used a combination of parylene C and parylene N to bind the thick embedded magnetic film. The

conformal coating obtained from the hybrid parylene increases the particle concentration while providing a strong binding which results in H_C of 440 kA/m, B_r of 0.8 T and $(BH)_{max}$ of 87 kJ/m³. In order to avoid plasma based or vacuum processes for locking the particles, Lisec et. al. [78] recently utilized low temperature atomic layer deposition (ALD) to develop rigid magnetic microstructures.

The advantage of such dry-pressed magnetic powder deposition process is that very thick (> several hundreds of μm to a mm) micro-structures can be obtained in a low-cost manner. Also, the magnetic properties (Fig. 4) obtained using this method is the closest to one can get to that of the bulk, sintered magnets using various state-of-the-art techniques. However, the use of loose particles are often not advisable in a cleanroom environment but the process is rather compatible to common back-end-of-line (BEOL) cleanroom environment.

Apart from magnetic alloys and powder-based structures, the development of more advanced magnetic nano-structures comprising two (or more) materials such as bi-magnetic core/shell particles [103] or multilayer structures [104] is currently being pursued extensively in order to gain fundamental understanding and for useful applications. In these systems, the exchange interaction between both constituents introduces an extra degree of freedom to tailor the overall properties [105]. The behavior of these systems can be understood as a combination of the intrinsic parameters of the hard and soft phases. Usually, soft materials possess low anisotropy K , which results in a small coercivity (H_C) with a large saturation magnetization (M_S). On the other hand, a hard material usually has a large K and moderate M_S values. In exchange-coupled hard-soft thin film systems, the magnetization switching behavior and consequently the $M(H)$ loop, depend strongly on the dimensions of the soft phase (in thin films, the thickness of the soft layer, t_{soft}). For a thin film there is a critical thickness (t_{soft}) below which the soft phase is rigidly coupled to the hard phase, and the two phases reverse at the same nucleation field, H_N , resulting in a rectangular hysteresis loop. Such systems are considered as completely exchange coupled where $(BH)_{max}$ of the heterostructure is greatly improved due to contributing factors from both soft and hard phases. By contrast, for thicker soft layers, the soft phase demagnetizes at significantly lower fields and the switching is characterized by an inhomogeneous reversal, and the system is usually called an exchange-spring magnet. The value of H_N depends on the material parameters of both the hard and soft phases. The critical t_{soft} is found to be roughly twice the width of a domain wall, δH , in the hard phase: $\delta H = \pi(A_{hard}/K_{hard})^{1/2}$, where A_{hard} and K_{hard} are the exchange stiffness and anisotropy constants, respectively, of the hard phase. Among different exchange coupled systems, Co/CoO [103], SmCo/Fe [106], NdFeB/Fe [107] are popular. Jiang and Bader [108] utilized a micromagnetic model to assess the potential of various exchange-coupled structures for maximizing the $(BH)_{max}$ and found out that the multilayer geometry and the

soft-cylindrical cores-in-hard-matrix-shell geometry have the highest achievable $(BH)_{\max}$. The multi-layer structure is also more suitable and achievable using current MEMS related processes. However, developing thick magnetic structures comprising of alternating layers of soft and hard phases with precisely controlled thickness remains a challenge.

In summary, all the integratable approaches to develop permanent magnets have both pros and cons. Electroplated magnetic alloys (whether heat treated or not), possesses much inferior magnetic properties such as lower coercivity and energy product as compared to the rare-earth based counterparts. Rare earth magnets are prone to oxidation and corrosion and it is difficult to pattern them employing the standard lithography techniques. Most of the better performing sputtered or electroplated films are limited in the range of few to few tens of μm in thickness due to the intrinsic stresses that develop during deposition and/or thermal mismatch stresses that arise during annealing steps. Also, the magnetic properties degrade with thickness as the grain size and shape varies. To overcome this problem, magnetic lamination techniques [109] are used where alternative layers of ferro-magnet and non-magnet (such as Cu) are deposited to increase the thickness while retaining the magnetic performance level.

C. Micro-scale Magnetic Pole Patterning Techniques

Another important aspect from the device application point of view is the necessity to develop differently polarized permanent magnets in a single substrate for maximizing the flux gradient (i.e. to increase the term $\frac{d\phi}{dz}$ in equation 7). This challenge plays a very important role in the poor performances of the completely integrated EM VEH devices as there is hardly any scope to alter the magnetic flux lines rather than using an omni-directional micro-magnet. Yamaguchi et. al. [40] developed an EM VEH device by utilizing a bipolar magnetic array. They developed fine patterned (pole intervals – 200 μm) alternating magnetized bipolar magnetic structure. The batch fabrication process of bipolar magnet array is composed of processing of two wafers with interdigitated comb structures having S-pole and N-pole magnetizations and finally wafer bonding of two diced pieces of S-pole and N-pole magnets. Oniku et. al. [110] proposed a novel methodology to develop fine scale micro-magnetic pattern with alternate polarity (Fig. 5(a)) using a magnetization mask. First, the hard-magnetic film was pre-magnetized to induce a magnetic polarization everywhere on the layer. Then, the magnetizing mask (which has the desired pattern) is brought in contact with the developed magnetic film, and a pulsed magnetic field is applied in the opposite direction. Because of the differences in relative permeability created by the features on the mask, the external reversal magnetic flux is concentrated in the areas of the soft magnetic mask. Consequently, the magnetization of selected regions is reversed, and the desired pattern is transferred onto the hard-magnetic layer. The authors later successfully magnetically patterned stripes with widths of 50 μm into 15 μm thick electroplated CoPt films and 5 μm thick NdFeB films

using a 7 μm thick, electroplated CoFe magnetizing masks. A major challenge that could arise in this process is that the magnetic flux lines might diffract from the soft magnetic mask and that could possibly change the magnetization map. Hence the process needs to be optimized before it can be taken to the device fabrication level. Dumas-Bouchiat et. al. [111] reported a thermomagnetic patterning (TMP) technique producing spatially modulated stray fields. The idea behind this approach is to exploit the temperature dependence of coercivity to switch the magnetization. In the TMP process (Fig. 5(b)), the hard-magnetic film to be patterned is initially saturated in one direction. The film is then locally heated by laser irradiation through a mask. During irradiation, a magnetic field is applied in opposite to the direction of the initial magnetization. The strength of the applied field ($\mu_0 H_{\text{applied}}$) is such that the total field, $\mu_0 H_{\text{total}}$ (applied field + demagnetizing field), acting on the magnetic film is less than $\mu_0 H_{\text{applied}}$ (at room temperature). The temperature at the film's surface rises quickly and heat diffuses through the film. When the exposed regions heated up to a certain temperature (say T) above the room temperature, $\mu_0 H_{\text{total}}$ overcomes $\mu_0 H_C(T)$. This causes the switching of the magnetization in these regions. The resultant structure consists of an array of oppositely magnetized micro-magnets. Uniaxially magnetized chessboard and stripe patterns with lateral feature sizes in the range 50 - 100 μm were produced using this method up to a depth in the range of 1.1 - 1.2 μm . Thus, just like the magnetization mask method, TMP technique is promising but the potential is yet to be proved for thick magnetic micro-structures as needed for EM VEH applications.

D. Design Challenge for Micro-scale Magnetic EH Device and Proposed Design Strategies

The problem with permanent micro-magnets for EM VEH or

most MEMS applications extends beyond just high energy product material development or process integration and relates to the lack of intelligent design strategies. When a relatively thin film/block of permanent magnet is used in a MEMS device as source of magnetic field, the stray magnetic field appears only from the edge of the magnet and a large part of the material is wasted. This is due to the presence of the shape dependent demagnetization field which acts to demagnetize the magnet in a direction which is opposite to the direction of the magnetization reducing the overall magnetic flux density [112]. Hence, the magnetic flux density also diminishes due to the demagnetizing field. In a magnet of finite length, demagnetizing field arises because of the free magnetic poles at the terminating ends of the magnet. This strength of the demagnetization field is dependent on the magnetization and the physical magnet shape. A commonly used approximation is to assume that the demagnetizing field H_d is uniform and opposite in direction to the magnetization,

$$H_d = -DM \quad (9)$$

where, D is the demagnetization factor, which has a value between 0 and 1 depending on shape of the magnet. Also, the energy product is a shape-dependent property of a magnet and can be expressed as [112]

$$(BH) = \mu_0 D(1 - D)M_s^2 \quad (10)$$

Thin films with perpendicular and parallel magnetization have $D \approx 1$ and $D \approx 0$, respectively, and both correspond to vanishing energy products. Hence, uniformly magnetized thin films produce no stray field outside the magnet, except at the edges, and most of the magnetic material is wasted. Hence, when a uniformly deposited magnetic block/film is used as a flux-source, the magnetic flux intensity is greatly reduced which affect the performance of integrated magnetic transducers.

However, if we replace a block of permanent magnet by micro-patterned array of magnets, the demagnetization effect can be minimized significantly and the magnetic stray field can be enhanced [93]. Hence, the magnetic flux density can be intensified over a small space due to increase of the edges of magnetic elements. In order to demonstrate the substantial advantage of optimized, micro-patterned magnetic structures compared to a block of integrated magnet, a novel device topology of micro EM VEH is adopted as shown in Fig. 6(a). The device consists of a micro-fabricated silicon spring structure (natural frequency – 500 Hz) with integrated double layer electroplated copper (144 turns, 190 Ω internal resistance [55]) and a separate substrate containing different micro-patterns of NdFeB magnets. The two substrates can be bonded with required alignments to develop a complete micro-scale EM VEH device. The magnetic arrays are placed only above one side of the coil so that the later can move from a region of high magnetic flux density to zero flux density, generating large flux gradient vis-à-vis induced voltage. The generated voltage

can be expressed as

$$V = Nlv(B_a - B_b) \quad (11)$$

Where N is the number of coil turns, l is the length of each rectangular coil, v is the velocity of the magnet, B_a and B_b are the magnetic flux densities in the coil plane above the magnetic arrays and in the no magnet region respectively. The electrical power that can be transduced is given by $P_L = \frac{v^2}{2R_L}$ (R_L is the matched load resistance).

TABLE I
DIFFERENT PARAMETERS FOR THE PROPOSED TOPOLOGIES

Components	Parameters	Values	
Mechanical Spring	Resonance Frequency	500 Hz	
	Inertial Mass	6.14×10^{-5} kg	
	Footprint	6×6 mm ²	
Micro-coil	Number of Turns	144	
	Coil Resistance	190 Ω	
Micro-magnets	Magnetic Remanence	0.6 T	
	Magnetization	Perpendicular	
	Shape	Dimensions	
	Block	Lower Thickness	Higher Thickness
	Block	$1600 \times 700 \times 50$ μm^3	$1600 \times 700 \times 250$ μm^3
	Square Patterns	$50 \times 50 \times 200$ μm^3 Interspacing: 50 μm	$50 \times 50 \times 1000$ μm^3 Interspacing: 50 μm
	Circular Patterns	$\emptyset 50 \times 255$ μm^3 Interspacing: 50 μm	$\emptyset 50 \times 1273$ μm^3 Interspacing: 50 μm
	Sripe Patterns	$1600 \times 50 \times 100$ μm^3 Interspacing: 50 μm	$1600 \times 50 \times 500$ μm^3 Interspacing: 50 μm

By changing the magnetic structure from block to square patterns to circular patterns to stripes, we have studied, using the COMSOL Multi Physics solver, the maximum output power that can be obtained. One important point about our simulation study is that we have kept the total magnetic volume constant in each case even if the pattern shapes are altered. We have considered two different thicknesses for the magnetic block/film – 50 μm (which is achievable using conventional thin film deposition processes) and 250 μm (which can be obtained using powder based bonded magnets). The thicknesses of the patterned structures are altered accordingly to keep the total volume same as that of the block/film magnet. The details of the design parameters are listed in Table I. It is observed from Fig. 6(b) that the maximum power is generated for the stripe patterned structures for lower thickness of the magnets. This is due to the fact that the number of edges parallel to the coil direction is maximized with the stripe patterns as compared to the square or circular ones which have edges in perpendicular to the coil directions producing detrimental effects. For thicker magnets (which can be developed using powder bonding methods), the maximum power is, however, obtained for

magnetic block structure than any other patterns (Fig. 6(c)). This can be attributed to the fact that demagnetization effect is reduced with the increase of magnet thickness whereas the interference between the stray fields of adjacent relatively thicker patterns plays destructive role in the overall flux density for the patterned structures.

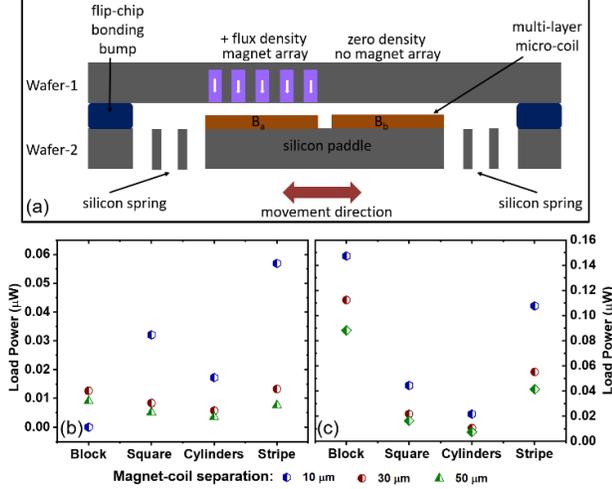

Fig. 6: (a) Schematic of a simple integrated EM VEH device. Comparison of output power for various micro-pattern shapes with block height of (b) 50 μ m and (c) 250 μ m.

The above-mentioned topology (Fig. 6(a)) can be further improved by adding additional manufacturing complexities. Such improvements and the required manufacturing complexities are shown in Table II. We have magnetic structures only on one side of the coil in the topology of Fig. 6(a). However, magnetic structures with completely opposite polarity can be deposited on the other side of the coil and these multiple polarities of the magnet on the same substrate can be induced using any of the methods described in the section III.C. Similar substrate containing differently poled magnetic structures can be wafer bonded on the back side of the coil wafer, which will further improve the flux linkage in the coil. Similar topology has been used previously for macro-scale EM VEH devices by assembling discrete components. This, however, will require highly precise multiple wafer bonding for accurate placing of the magnets with respect to the coil. Finally, the magnetic flux loss on the outer sides can be reduced by adding a soft magnetic layer, such as Permalloy (which can be easily deposited using MEMS compatible processes [128]) of 5 μ m thickness. Through all these additional steps, the output power can be improved over an order of magnitude which is summarized in Table II. We have calculated the output power for the most optimized magnetic structures of 50 μ m (i.e., stripes) and 250 μ m (i.e., block) thicknesses as obtained from Fig. 6. We found that maximum output power for our proposed topology is 3.3 μ W at an acceleration of 1g, which is significantly higher than other reported fully integrated MEMS EM VEHs mentioned in section II. However, this is just an

estimation and certain parameters will vary according to the real experimental conditions. Also, the output can be further enhanced through material improvements, topology modifications and required optimizations. While our analysis is mainly focused around the planar coils, the utility of micro-patterning for a serpentine coil topology was demonstrated experimentally by Yamaguchi et. al. [40].

The above analysis definitely shows a bright road ahead for micro/nano-magnetics enabled EM VEHs. Hence, we can conclude that one must be careful while designing integrated EM VEH devices. The combined knowledge of materials, process technologies and design rules can improve the overall performance dramatically.

IV. ROLE OF MAGNETICS IN MICRO-SCALE POWER CONVERSION AND MANAGEMENT

Efficient energy conversion and management is as important as the energy generation for the development of the autonomous sensor nodes. The amplitude of the generated voltage (AC or DC) from any EH device varies with time whereas most of today's circuitry operate under a regulated DC power supply. Therefore, the power electronics is an integral part of any EH system to enable a complete autonomous energy source. Challenges in the power management of harvested energy vary according to the utilized energy conversion technique due to different output impedances (a few Ω to tens of $M\Omega$), voltage levels (mV to 10s of V), and operating frequencies (1 Hz to 10 kHz). Szarka et. al. [113] provided detailed review of different rectification and power conditioning techniques. Apart from these design challenges, a major task is related to the development of micro-magnetic components compatible with integrated circuit (IC) processes with performance similar to the discrete counterparts [114]. This is important not only to cope up with the continuous trend of miniaturization of solid-state devices but also to improve the overall efficiency of the conversion circuit. However, most of the reported interface circuits use off-chip inductor or transformer, which results in increased size and cost [115-117]. Hence, development of on-chip magnetic passives while maintaining higher efficiency is a major bottleneck towards realization of monolithically integrated Power Management IC (PMIC). Recently, a group from Massachusetts Institute of Technology demonstrated first fully-functional integrated power converter designed to interface a MEMS-based EM VEH [118]. Their IC performs the conjugate impedance matching for maximum power extraction along with resonant frequency tuning and AC to DC voltage conversion. Also, cold startup from 150 mV AC is accomplished using an on-chip Meissner oscillator with an off-chip transformer, clearly showing the requirement of high performance integrated magnetic passives. A number of review papers [114,119-120] have been published over the years discussing state-of-the-art for on-chip magnetic passives targeting power supply in package (PwrSiP) and power supply

TABLE II
COMPARISON OF DIFFERENT TOPOLOGIES IN TERMS OF FABRICATION COMPLEXITIES AND IMPROVED PERFORMANCES

Topology	Manufacturing Complexities	Output Power	
		Lower Thickness	Higher Thickness

on-chip (PwrSoC) applications. In the following paragraph, we summarize the role of MEMS based thin film magnetics for improving the efficiency of the passives along with the different challenges and outlooks.

In pursuit of miniaturization, magnetic device integration can be achieved at various levels: wafer, package, and board [114]. At very high switching frequencies (>50 MHz), the required inductance value is compatible with the air-core inductors but there are several technical challenges involved. The absence of magnetic core worsens the overall power system efficiency, as the magnetic field of an air-core inductor can couple with the substrate of an IC at very high frequency, causing a latch-up or an unpredictable behavior of the underlying circuit [121-122]. In general, air-core inductors have low coupling and low inductances, whereas the magnetic-core components permit higher energy storage and higher inductances with the drawback of higher power losses due to hysteresis and eddy currents, and core saturation [119]. To achieve a reasonable enhancement of the air-core inductance, soft magnetic materials

are used as the core. It helps to provide high magnetizing inductance and good coupling factor between the primary and secondary windings for transformers/coupled inductors. The following characteristics are ideally needed out of the magnetic material, at frequencies in the range of 10 to 100 MHz and higher for further miniaturized and efficient magnetic passives: lower core loss, higher saturation flux density, higher anisotropy field, lower magnetostriction and higher permeability [114,119]. Core losses, which consist of eddy current losses and hysteresis losses, can be reduced by using high resistivity and low coercivity soft magnets. Particularly, core material with high resistivity is needed to control the eddy current effects. Eddy currents accounts for the dissipative energy loss in the core and define the maximum frequency of operation for the inductor. Additionally, a high resistivity material increases the skin depth to ensure that the magnetic field intensity does not vary with the thickness of the magnetic film. In order to minimize the hysteresis loss at high frequencies, low coercivity is needed. High saturation magnetization is required to enhance the current handling

capability of the inductor, while relatively high, constant permeability at high frequencies along with high anisotropy field is desired for increased inductance and stable high frequency performance. In order to maintain the above-mentioned properties, it is also important to develop processing techniques that are cost-effective and compatible with MEMS/CMOS fabrication for the incorporation of magnetic materials in micro-magnetic devices. Various techniques have been investigated over the years to deposit soft magnetic materials such as electrodeposition, sputtering, screen printing etc. Screen-printing is low cost and ideally suited for non-metallic thin film (soft ferrites – NiZn, MnZn etc.) deposition [123]. However, requirement of high temperature, post-processing annealing is not suited for MEMS applications. Sputtering has the advantage of depositing a wide range of magnetic materials, including alloys and oxides, such as CoZrNb, FeCoBC, FeCoBN, FeCuNbSiB, CoZrTa, CoP, Permalloy etc [124-127,135-136]. Sputtered magnetic alloys have the advantage of higher saturation flux density and permeability at CMOS compatible temperatures providing uniform and controlled deposition. Low-cost, electroplated magnetic films are good for achieving thick core layers and the process is ideal for building 3D device structures. The most commonly used electrodeposited magnetic material is permalloy ($\text{Fe}_{81}\text{Ni}_{19}$), which has a combination of relatively high permeability, low hysteresis losses and near-zero magnetostriction [128]. Other electrodeposited core materials include $\text{Ni}_{45}\text{Fe}_{55}$, CoNiFe, CoP etc [129-131]. However, no single material can have all the required properties of high resistivity, high flux density, high permeability and low coercivity, and can be used as the core in micro-inductors for all DC/DC converters. At low frequencies (1 MHz), ferrites are most commonly used, while at higher frequencies (> 5 MHz), magnetic thin films with higher flux density and lower coercivity are better suited. As the switching frequencies go up to 100 MHz, magnetic thin films can provide an efficient solution as core material for passive technology. However, eddy current losses become a significant concern at such switching frequencies. Then, techniques such as magnetic laminations become crucial to develop thick films while maintaining high resistivity to counter the eddy current losses [132].

In terms of topology, spiral, toroidal and solenoidal micro-inductors are widely used. The relative advantages and disadvantages of each topology are discussed by O’Mathuna et. al. [114]. With the continuous advancement of magnetics technologies, the efficiency of micro-magnetic passives is increasing rapidly. Such trend would be ideally suited for the drive towards miniaturized, monolithically integrated power conversion circuits leading to the system integration of EH powered systems.

V. CONCLUSION

Micro-scale energy harvesting has advanced rapidly in the two decades owing to the advancements in MEMS and

microsystem technologies. However, magnetics-based systems have faced several challenges in both fundamental and technical fronts, which have restricted the number of reported works in this area significantly compared to its other counterparts. However, magnetic MEMS/micro-systems technologies have progressed equally but focusing other application areas. These two parallel streams of advancements must be merged in order to gain the most from the promising magnetic VEH and power conversion technologies which are of paramount importance as powering solution for autonomous and ubiquitous sensor nodes within the emerging ‘IoT’. The purpose of this paper is to develop a roadmap based on micro/nano-magnetics for building high performance energy harvesting and power conversion devices. While doing so, we also addressed the current status in this field, the fundamental limitations and technical challenges that have emerged. Based on our analysis, the prospect of micro-scale EH devices are quite bright and such devices along with miniaturized power conversion circuits can potentially lead to system integration of complete EH system leading to autonomous ‘IoT’.
